Abstract. A key component of subduction initiation rock suites is boninite, a high-magnesium andesite that is uniquely predominant in western Pacific forearc terranes and in select Tethyan ophiolites such as Oman and Troodos. We report, for the first time, the discovery of low-calcium, high-silica boninite in the middle Eocene Zambales ophiolite (Luzon Island, Philippines). Olivine–orthopyroxene microphyric high-silica boninite, olivine–clinopyroxene–phyric low-silica boninite and boninitic basalt occur as lapilli fall deposits and pillow lava flows in the upper volcanic unit of the juvenile arc section (Barlo locality, Acoje Block) of the Zambales ophiolite. This upper volcanic unit overlies a lower volcanic unit consisting of basaltic andesite, andesite to dacitic lavas and explosive eruptive material (subaqueous pahoehoe and lobate sheet flows, agglutinate and spatter deposits) forming a low-silica boninite series. The overall volcanic stratigraphy of the extrusive sequence at Barlo resembles holes U1439 and U1442 drilled by IODP Expedition 352 in the Izu–Ogasawara (Bonin) trench slope. The presence of depleted proto-arc basalts in the Coto Block (45 Ma) (Geary et al., 1989), boninite and boninite series volcanics in Barlo (Acoje Block (44 Ma)) and simultaneous and post-boninite moderate-Fe arc tholeiites in Sual and Subic areas of the Acoje Block (44–43 Ma) indicate that the observed subduction initiation stratigraphy in the Izu–Ogasawara–Mariana forearc is also present in the Zambales ophiolite. Paleolatitudes derived from tilt-corrected sites in the Acoje Block place the juvenile arc of northern Zambales ophiolite in the western margin of the Philippine Sea plate. In this scenario, the origin of Philippine Sea plate boninites (IBM and Zambales) would be in a doubly vergent subduction initiation setting.

1 Introduction

As the surface manifestation of a convecting mantle, subduction zones play a fundamental role in material transfer from the surface to the deep interior and vice versa. Early in Earth’s history, the transition from a stagnant lid regime to the present mode dominated by plate forces necessitates subduction initiation. Numerical models show that plate tectonics or mantle overturn in terrestrial planets can be triggered by narrow plumes impinging on weakened crust inducing gravitational instability and slab descent (Cramer and Tackley, 2016; Gerya et al., 2015). Internally driven mechanisms such as plume-induced subduction initiation (Whattam and Stern, 2015), however, are fundamentally different from end-member models of Cenozoic subduction initiation which rely on preexisting zones of weakness such as fracture zones and transform faults or require lithospheric collapse (Stern,
2004). How subduction begins in the oceanic domain is one fundamental issue yet to be fully deciphered, thus it is regarded as a high priority scientific target (Challenge No. 11) of the International Ocean Discovery Program (IODP) for 2013 to 2023. Understanding this volcanic and tectonic process is hampered by its transient nature, with few examples in the geologic record with the exception of submarine active and paleo-forearcs and terrestrial supra-subduction ophiolites.

In testing subduction initiation models, the Izu–Ogasawara (Bonin)–Mariana (IBM) forearc region remains as one the most appropriate localities; this is due to its temporally distinct volcanic record of oceanic accretion and juvenile arc magmatism immediately following the onset of subduction. After the subduction of the Pacific Plate beneath the Philippine Sea plate commenced at 52 Ma, magmatism progressed from 52 to 48 Ma mid-ocean ridge basalt (MORB)-like proto-arc basalts (or forearc basalts) to 48–44 Ma boninite and boninite-series volcanics, followed by 45–35 Ma arc tholeiites and calc–alkaline lavas (Ishizuka et al., 2011; Kanayama et al., 2012; Reagan et al., 2010). The widespread occurrence of subduction initiation rock suites along the eastern margin of the Philippine Sea plate is summarized in Fig. 1a. Basalts of similar composition and age range to proto-arc basalts dredged along the Mariana and Bonin trench slopes were found at IODP Expedition 351 Site U1438 in the Amami Sankaku Basin (Arculus et al., 2015; Ishizuka et al., 2018). This indicates that the Oligocene Kyushu–Palau Ridge (KPR) intra-oceanic arc is built upon an igneous basement that formed part of the earliest seafloor spreading event related to subduction initiation. The subsequent late Oligocene opening of the Shikoku–Parece Vela Basin resulted in its present configuration with Site U1438 in the back-arc side of KPR. Based on dredging and dive observations in the forearc trench slope, proto-arc basalts are found at deeper depths relative to boninites which occur upslope and subaerially at Chichijima (type locality) and Moku-jima island groups (Ishizuka et al., 2011; Kanayama et al., 2012; Umino and Nakano, 2007). The hypothesis that proto-arc basalt lies stratigraphically below boninite has been suggested by IODP Expedition 352 based on four sites drilled in the trench-side slope of the Bonin Ridge (Reagan et al., 2015, 2017). Both spontaneous and induced initiation have been replicated in numerical models of incipient subduction at the IBM. Earlier models with imposed plate velocities generally focused on initiation across a preexisting weak zone, and combined with melting models could reproduce the observed proto-arc basalt–boninite stratigraphy (Hall et al., 2003; Leng et al., 2012). Subsequently, spontaneous subduction initiation has been shown to be plausible with compositional density contrast being provided by the thickened middle crust of relic Cretaceous arc terranes (Leng and Gurnis, 2015). So far, neither spontaneous nor induced initiation models can uniquely explain the subduction initiation that produced the IBM forearc and the mechanism remains elusive (Keenan and Encarnación, 2016).

Here an alternative approach to exploring subduction initiation processes in the western Pacific region is presented. Following Stern et al. (2012), this study focuses on the middle Eocene Zambales ophiolite in the Philippines as it offers a ∼3200 km² exposure of Eocene supra-subduction oceanic lithosphere. Most of the Jurassic to Cretaceous ophiolites that form basement complexes in the eastern Philippines are increasingly recognized as complementary features to Cretaceous terranes in the northern Philippine Sea plate (e.g., Amami Plateau, Daito Ridge) possibly sharing a common history as the overriding plate prior to initiation of subduction (Billedo et al., 1996; David et al., 1997; Deschamps and Lallemand, 2002; Lallemand, 2016). Therefore, juxtaposed Eocene ophiolites are potential targets to investigate subduction initiation as a plate-scale process. Regional tectonic reconstructions predict the interaction of a pre-Eocene ocean basin located east of Eurasia and the western margin of the Philippine Sea plate (Wu et al., 2016). Coincidentally, aside from the IBM forearc region, the Dasol–Barlo locality in northern Zambales ophiolite is where middle Eocene boninitic rocks are also reported (Evans et al., 1991; Florendo and Hawkins, 1992; Hawkins and Evans, 1983). The significance of Zambales ophiolite as an analogue of the IBM forearc has been recognized since the early 1990s (Pearce et al., 1992) yet this connection remains unexplored. Motivated by how the ophiolite concept progressed through studies of the IBM forearc, we present field, petrologic and geochemical characterization of a juvenile arc section in northern Zambales ophiolite to evaluate subduction initiation and boninite petrogenesis in a regional geodynamic context.

2 Geologic background

Located in western Luzon, the structurally coherent Zambales ophiolite is a representative supra-subduction ophiolite of the western Pacific and the largest in the Philippines (Fig. 1b). The ophiolite spans the entire Zambales mountain range from 16 to 14.7° N where it partly underlies stratovolcanoes of the Luzon Arc, including Mt. Pinatubo. It consists of three fault-bound massifs, namely Masinloc, Cabangan and San Antonio, which each preserve complete ophiolite internal stratigraphy. The ophiolite is flanked by the Central Valley basin (CVB) to the east and West Luzon basin to the west. Late Eocene to late Miocene Aksitero and Moriones formations of the CVB record the transition from a hemipelagic, deep marine setting to a shallower environment dominated by ophiolite-derived sedimentation signaling the uplift of the ophiolite; while sedimentary sequences west of the ophiolite, the Cabaluan and Sta. Cruz formations, indicate that terrane docking and large-scale uplift had transpired by the Pliocene (Karig et al., 1986; Schweller et al., 1984). Sporadic chert slivers with late Jurassic–early Creta-
Figure 1. (a) Distribution of subduction initiation rock suites in the Philippine Sea plate and spreading histories of associated marginal basins (Deschamps and Lallemand, 2002; Pearce et al., 1992; Reagan et al., 2017). (b) Regional geological map of the Zambales ophiolite after Yumul et al. (1990) with whole-rock K–Ar and zircon U–Pb ages from Fuller et al. (1989) and Encarnacion et al. (1993). The 44–43 Ma Acoje Block consists of the northern Masinloc Massif and the southernmost San Antonio Massif. The enclosed region (red box) is the Barlo extrusive section mapped in this study.

ceous radiolarian fauna are found in the westernmost margin of the ophiolite (Hawkins and Evans, 1983; Karig et al., 1986; Queaño et al., 2017b). Similar Mesozoic cherts associated with disrupted ophiolitic fragments in northern Luzon highlight the existence of a shear zone (west Luzon shear zone) west of the ophiolite (Encarnación, 2004; Karig, 1983; Queaño et al., 2017a).

Petrologic, geochemical and isotopic studies reveal that the Zambales ophiolite represents two distinct mantle–crust sequences: the 45.1 Ma Coto Block with affinity transitional to mid-ocean ridge basalt (MORB) and island arc tholeiite (IAT), and the 44.2–43.7 Ma Acoje Block with island arc characteristics (Encarnación et al., 1999, 1993; Geary et al., 1989; Hawkins and Evans, 1983; Yumul, 1990). The existence of a NNE–SSW trending structural boundary previously characterized by Hawkins and Evans (1983) as a left-lateral fault between Acoje and Coto blocks within the Masinloc Massif is supported by gravity and magnetic data with anomaly contrasts which extend at depth (Salapare et al., 2015). Although the juvenile arc character of Acoje Block and the supra-subduction origin of Zambales ophiolite are clear, the crustal nature and tectonic environment of Acoje and Coto blocks remain unresolved. The Acoje Block as defined by Yumul et al. (1990) consists of the northern Masinloc Massif and the San Antonio Massif while the Coto Block consists of the southern Masinloc Massif and the Cabangan Massif (Fig. 1b). The present disposition of the Acoje Block is postulated to be the result of the southward translation of San Antonio Massif with respect to northern Masinloc Massif (Yumul et al., 1998). Crustal thickness estimates, based on SW–NE transects of the northern Masinloc Massif, are up to 9.5 km for the mantle section and 7 km for the lower crustal section. The fertile to moderately depleted Acoje mantle section is comprised of harzburgite and lherzolite with spinel Cr# \( \text{Cr}/(\text{Cr} + \text{Al}) \) ranging from 0.18 to 0.56, generally increasing towards the mantle–crust transition zone (Evans and Hawkins, 1989; Yumul, 1990). Harzburgites from the uppermost mantle section are strongly depleted in light and middle rare earth elements (LREEs and MREEs) with equilibration temperature and oxygen fugacity estimates of 730°C and 1.9Δlog\( (f_O^2) \) units above the FMQ buffer, respectively (Tamayo, 2001). From the residual mantle section, the mantle–crust transition zone passes through interlayered ultramafic cumulates and dunite to layered cumulate gabbro-norite. The Acoje transition zone hosts podiform chrome deposits (Cr# = 0.71–0.77) and Ni–Cu sulfides, both of which are PGE-bearing (Bacuta et al., 1990). Refractory transition zone dunites,
characterized by spinel Cr# greater than 0.6, are interpreted to be of cumulate origin (Abrajano et al., 1989). The Acoje Block lower crustal section is dominated by cumulate gabbronorites with an olivine–clinopyroxene–orthopyroxene–plagioclase crystallization sequence. Coexisting plagioclase and clinopyroxene in gabbronorite are calcic (anorthite content \([\text{Ca}/(\text{Ca} + \text{Na} + \text{K})] = 0.89–0.94\) and magnesian \((\text{Mg}/(\text{Mg} + \text{Fe})) = 0.80–0.87\). In addition to petrological criteria discussed above, the arc affinity of Acoje Block has been demonstrated using immobile element–based geochemical fingerprinting of volcanic and hypabyssal rocks, as well as constituent clinopyroxene (Yumul, 1996). A regional scale, the ophiolite appears to have a domal structure with a north–south trending axis. The volcanic section of Acoje Block in the northern Masinloc Massif dips northwest and is unconformably overlain by middle to late Miocene sedimentary sequences.

3 Volcanic geology

Based on observations around the Barlo massive sulfide mine, two volcanic units with distinct lithofacies are distinguished in the Acoje Block extrusive sequence: a dominantly pyroclastic lower basaltic andesite–andesite unit overlain by an upper boninite unit with minor boninitic basalts. Here and in the succeeding sections, we use the term boninite as per the recommended IUGS criterion (Le Maitre, 2002). Pillow lavas that qualify as boninite based on MgO and TiO₂ contents but with less than 52 wt% SiO₂ are classified as boninitic basalts, equivalent to the “basaltic boninite” of Reagan et al. (2015). Structural measurements of bedding planes in 136 locations constrain the gross structure of the crustal sequence, consisting of a NE–SW trending doubly plunging anticline forming a dome structure and NW-plunging anticline (Fig. 2). Estimated thickness of the upper unit and lower volcanic units are 680 and 520 m, respectively.

South of Barlo mine, boninite dike swarms with conjugate intrusives directions change into a succession of submarine explosive volcanic deposits. In order of ascending stratigraphic level, the lower basaltic andesite–andesite unit consists of tuff breccia with block-sized pyroclasts, subaqueous pahoehoe lava flows withropy wrinkles and stretched vesicles on lobe crust (Umino et al., 2002, 2000) (Fig. 3f), moderately welded agglutinate, welded scoria and spatter deposits marginal to a NW–SE trending fissure vent, and an uppermost subaqueous fallout deposit of glassy lapilli tuff (Fig. 3e). In places, tuff breccia is cut by NE-dipping boninite dikes. The dominant occurrence of flat pahoehoe lobes suggest the preexistence of subhorizontal topography (Umino et al., 2002). The volcanic facies recognized in the upper section of the lower volcanic unit (agglutinate, scoria and spatter deposits surrounding fissure vent) are characteristic of intermittent submarine Strombolian to Hawaiian-style fountaining (Head and Wilson, 2003).

NW-dipping boninite tuff breccia and pillow lavas of the upper unit (Fig. 3b) overlie hyaloclastite, spatter deposits and pillow lavas (Fig. 3c) of the lower basaltic andesite–andesite unit at an exposure north of Mt. Sol. A sill directly above lower unit pillow lavas has a whole-rock K–Ar age of 44.1 ± 3.0 Ma (Fuller et al., 1989). Pillow lavas of the upper and lower unit show distinct morphological features based on measurements of vertical \((V)\) and horizontal \((H)\) axes following the method of Walker (1992). Pillow lavas of the upper unit are marked by lower aspect ratios \((n = 92, \text{median } H = 0.53 \text{ m}, \text{median } V = 0.34 \text{ m})\) compared to boninitic basalts of the upper unit which are elongate \((n = 15, \text{median } H = 0.74 \text{ m}, \text{median } V = 0.32 \text{ m})\). Southeast of Barlo mine, NE-dipping pillow lavas of the upper unit are overlain by middle-late Eocene radiolarian-bearing claystone (Schweller et al., 1984). Further southwest in a synclinal area with upright structures preserved, a ~30 m high boninite pillow volcano is recognized (Fig. 3d). It consists of flattened flow lobes in the summit with pillow lavas dipping downslope along its flanks. This volcanic construct is one of several discrete boninitic volcanic edifices rising above the lower unit. Elsewhere, these pillow lavas are cut by SW-dipping dikes with glassy margins and overlain by glassy boninite lapilli tuff fall deposit (Fig. 3a).

4 Sampling and analytical methods

A total of 152 samples were collected during the 2016 mapping campaign. For this study, a subset of 44 samples located along NW–SE transects of the Acoje Block volcanic sequence at Barlo were selected for whole-rock geochemical analyses and screened through visual and microscopic assessment of secondary alteration. Location of samples is shown in the geologic map in Fig. 2. Rock slabs were cut to remove altered surfaces. Initially, slabs were crushed coarsely to manually separate low temperature secondary minerals such as quartz and calcite. The coarse crushing step was followed by rinsing with deionized water and drying in an oven at 110°C for at least 12 h. An iron mortar and an agate mill were used for fine crushing and grinding, respectively. Ignition loss is taken as the normalized weight loss after ignition of ground rock powder at 900°C for 4 h. Major element compositions were determined by X-ray fluorescence (XRF) spectrometry using a PANalytical Axios spectrometer at the Geological Survey of Japan/National Institute of Advanced Industrial Science and Technology. Glass beads were fused using a Tokyo Kagaku bead sampler (TK-4500) at a 1:10 dilution ratio as mixtures of 0.5 g (±0.0002) rock powder and 5 g (±0.001) lithium tetraborate alkali flux (Li₂B₂O₇, Merck Spectromelt A10). Precision, measured as percent relative standard deviation (%RSD), was better than 2% based on repeated measurements of JB-2, BIR-1 and BHVO-2; accuracy was also better than 2%. Trace element (REE, V, Cr, Ni, Li, Be, Rb, Sr, Y, Zr, Nb, Cs, Ba, Hf, Ta,
Pb, Th and U) concentrations were determined by inductively coupled plasma mass spectrometry (ICP-MS) using an Agilent 7900 instrument also located at the Geological Survey of Japan. Samples were digested for at least 48 h on a hotplate using screw top Teflon beakers with a mixture of HF and HNO3 at a 5:1 ratio. Dissolution procedures were performed in a Class 1000 clean laboratory. Twelve international standards (BIR-1, BRR-1, JB-2, JB-3, JA-1, JGb-1, JA-2, BCR-1, AGV-1, JB-1a, BHVO-2 and BE-N-1) were used to construct calibration lines. Standard JB-2 and JB-3 solutions at similar dilution levels were used as external standards. Reproducibility is better than 2% for REEs and better than 3% for the rest of the trace elements except for Ta (6.5%) and Be (3.6%). Mean percent error is generally within 5 to 10% relative to the preferred values of Jochum et al. (2016) and Dulski (2001).

Major element compositions of constituent mineral phases were determined with a JEOL-8800R electron microprobe at Kanazawa University using a 3 µm probe diameter, 20 nA probe current and 20 kV accelerating voltage. Natural (Kurose olivine and clinopyroxene) and synthetic mineral standards were used for calibration and data were corrected using the ZAF method.

5 Results

Representative mineral chemistry data are listed in Table S1 in the Supplement. Results of whole-rock major and trace element analyses are given in Table S2 with total Fe represented as Fe₂O₃. In succeeding discussions, all samples are normalized to 100% volatile free with total Fe recalculated as FeO* to enable comparison with compiled datasets.

5.1 Textures and phase chemistry

Zambales high-silica boninite (as defined in Sect. 5.2) is mostly aphyric and consists of subhedral olivine microphenocrysts (Mg# [Mg/(Mg+Fe²⁺)] = 0.88–0.91), abundant elongate enstatite microphenocrysts (Mg# = 0.86–0.89, WO₃ = 4.9–5.1) with augite (with or without pigeonite overgrowth) (Mg# = 0.67–0.84, WO₃ = 4.4–5.7), and chromian spinel (Cr# [Cr/(Cr+Al)] = 0.69–0.84,
Mg\# = 0.53–0.69) set in a glassy groundmass with feathery quench clinopyroxene (Fig. 4a–b). This assemblage corresponds to “Type II boninite” of Umino (1986) in samples described from the type locality at Chichijima Island, Ogasawara (Bonin) Archipelago in southern Japan. Unlike low-Ca, high-silica boninites from Ogasawara, clinoenstatite has not been identified so far. Comparative mineral chemistry of Zambales and Ogasawara boninite is shown in Fig. 5. Olivine, orthopyroxene and spinel compositions of Zambales and Ogasawara boninite are almost identical except for a limited range of olivine Mg\#, which is most likely due to the small number of samples analyzed (two for olivine and four for spinel), and lower spinel Cr\# in Zambales boninite (Taylor et al., 1994; Umino, 1986; Yajima and Fujimaki, 2001). NiO contents of olivine range from 0.18 to 0.41 wt % and plot on fractionation trends from the mantle olivine array. Subhedral olivine microphenocrysts in high-silica boninite (ZM2-100A) are zoned with magnesian cores. The range of spinel Cr\# of Zambales boninite overlap with Acoje podiform chromitites and transition zone dunites. Enstatite microphenocrysts with sieve texture and reverse zoning are recognized together with embayed quartz xenocrysts (Fig. 4c–e). Reversely zoned enstatite has oscillatory-zoned magnesian rims (Mg\# = 0.86–0.87) with resorbed and dissolved cores (Mg\# = 0.68–0.77). Similar xenocrystic quartz and sieve-textured enstatite have also been noted in Ogasawara boninite (Watanabe and Kuroda, 2000). Glassy olivine–phyric and olivine–clinopyroxene–phyric low-silica boninite varieties are also present (Fig. 4f). Hypocrystalline boninite pillow lavas consist of olivine, usually altered and replaced by chlorite and carbonate minerals, subhedral clinopyroxene phenocrysts, elongate orthopyroxene and plagioclase microphenocrysts.

Highly phyratic boninitic basalt has a phenocryst assemblage of olivine replaced by calcite, zeolite and clay minerals, euhedral to subhedral augite (Mg\# = 0.82–0.90, Wo\textsubscript{41–43}En\textsubscript{48–53}) with oscillatory and sector zoning, and rare corroded enstatite (Mg\# = 0.85–0.88, Wo\textsubscript{3}En\textsubscript{82–84}) with reverse zoning. Chromian spinel (Cr\# = 0.62–0.71) occurs near phenocryst margins and as inclusions in olivine. A peculiar zoning relationship of augite and enstatite demonstrates that some pyroxenes are xenocrysts in nature. Groundmass consists of less than 0.3 mm long plagioclase microlites with swallow-tail terminations, spherulitic clinopyroxene and altered interstitial glass totally replaced by clay minerals. Acicular zeolite occurs as vesicle fillings. We note that such tex-
ters have been described in samples reported as boninite by Evans et al. (1991).

Lower-unit basaltic andesite and andesite pillows and lapilli tuff are marked by the presence of abundant plagioclase laths as glomerocrysts and sparse cpx with or without opx microphenocrysts with two-pyroxene intergrowths in a glassy groundmass with plagioclase microlites and magnetite (Fig. 4g).

5.2 Whole-rock geochemistry

The Acoje Block extrusive section at Barlo is predominantly composed of basaltic andesite and andesite. Loss on ignition (LOI) values are generally between 4 and 7 wt % and total alkalis are less than 3 wt % (Table S2). Cs, Rb, K, Li, Ba and Mn contents in some dikes and pillow lavas, especially those collected nearest to the massive sulfide mine, are highly scattered and plot away from general fractionation trends shown by the majority of samples. The rest of the samples show variations in the major element and trace element compositions consistent with fractional crystallization; thus, the geochemical characteristics are deemed as primary. Pillow lava, tuff breccia and lapilli tuff of the upper volcanic unit and dikes from the uppermost section of the dike-sill complex are primitive with >8 wt % MgO and <0.5 wt % TiO₂, satisfying the IUGS criteria for boninite (Le Maitre, 2002). Following the classification of Kanayama et al. (2013) and Reagan et al. (2015) both high-silica (HSB) and low-silica (LSB) boninite subtypes are recognized (Fig. 6). This compositional division is consistent with petrographic observations, with HSB having olivine with orthopyroxene microphenocrysts and LSB with olivine or olivine with clinopyroxene phenocrysts. Boninitic samples previously described at Barlo are actually from the dike section and lower section of the upper unit and with sampling having been limited to Balincaguin River and the periphery of Barlo VMS mine (Evans et al., 1991; Hawkins and Evans, 1983; Tamayo, 2001; Yumul, 1990). Besides the low-silica boninite and boninitic basalt samples from previous studies with altered equivalents having more than 3.5 wt % Na₂O + K₂O, 3–5 wt % LOI and possibly up to 4 wt % SiO₂ enrichment, this is the first report of pristine high-silica boninite in the Zambales ophiolite. Boninite from Zambales (n = 14) have CaO / Al₂O₃ ratios less than 0.76, mostly within 0.63–0.71 with FeO⁺ / MgO ratios < 1 (Mg# values from 63 to 73). Ni and Cr contents are high, ranging from 72 to 292 and 145 to 727 µg g⁻¹, respectively. Boninitic basalts (n = 3) are primitive as well with 12.4–13.6 wt % MgO and 712–1113 µg g⁻¹ Cr.

Pillow lava and lapilli tuff of the lower volcanic unit and dikes from the deeper section of the dike-sill complex are andesitic in composition with 55.5–63.5 wt % SiO₂, 2.4–7.1 wt % MgO and 0.31–0.47 wt % TiO₂ (Fig. 6). These andesites (n = 26) are magnesian with Mg# mostly between 0.47 and 0.54, CaO / Al₂O₃ ratios < 0.63, FeO⁺ / MgO ratios > 1.16, and Ni and Cr contents are also low at 8–58 and 3–47 µg g⁻¹, respectively. MgO and SiO₂ compositions of lower unit volcanics and corresponding dikes lie above the island arc basalt (B)–basaltic andesite (BA)–andesite (A)–dacite (D) discriminant line of Pearce and Robinson (2010) and follow a curvilinear fractionation trend from low-silica boninite; thus, are recognized here as forming a low-silica boninite differentiation series (Fig. 6). Dacitic pillow lavas represent the differentiated end of the LSB series. A gap between andesitic boninite-series volcanics with < 60 wt % SiO₂ and dacite (62–63 wt %) is present. A single dike (B-47 d4) that cross cuts the LSB-series dikes is the only sample with > 0.5 wt % TiO₂. Although the pervasive clay alteration of samples from the Barlo massive sulfide mine hinders the direct characterization of the host rocks, the massive sulfide deposit is most likely hosted by the lower volcanic unit and possibly up to the lowermost section of the upper unit based on stratigraphic relationships and comparison of field and core descriptions (Paringit, 1977). The occurrence of massive sulfide-bearing horizons at Barlo is also consistent with massive sulfide mineralization in Oman, Troodos and Bonin Ridge which occur either below or within the boninitic volcanic section (Ishizuka et al., 2014; Umino et al., 2009).
Compositions of Zambales boninite and boninite series volcanics are marked by low incompatible trace element abundances relative to MORB (Fig. 7). Extended trace element patterns arranged after Pearce and Parkinson (1993) show the dominance of slab-derived components with notable enrichment in fluid-mobile elements (Cs, Rb, Ba, U, K, Pb, Sr, Li, Na) and depletion of high field strength elements (Nb, Ta). Hf shows a positive anomaly relative to Sm while Ti shows a negative anomaly relative to Y. In contrast with samples from Ogasawara that exhibit characteristic U-shaped chondrite-normalized rare earth element (REE) patterns, Zambales boninite and boninite-series volcanics exhibit spoon-shaped REE patterns with heavy REEs (HREE) at 5–15 times the chondrite values and weak negative Eu anomaly ($\text{Eu}^*/\text{Eu} = 0.9$). Boninitic basalts are more depleted in middle and heavy REEs with just three to five times the chondrite values. Excluding moderately altered samples, chondrite normalized La/Ce ($[\text{La}/\text{Ce}]_N$) ratios of Zambales and Ogasawara boninite are both less than one. The range of $[\text{Sm}/\text{Yb}]_N$ ratios, as measure of middle REE depletion relative to heavy REE, however, are distinct at 0.06–0.09 for Zambales and 0.02–0.05 for Ogasawara. The effect of fractionation in Zambales boninite samples is shown as increasing trace element abundances relative to a glassy olivine–phyric LSB (ZM2-107) with 12.4 wt % MgO. The evolved dacitic samples do not differ significantly with just twice the normalized REE abundances of the most primitive sample. Trace element pattern of a single dike (B-47 d4) with greater than 0.5 wt % TiO$_2$ is visibly different with muted fluid-mobile element enrichment without a negative Ti anomaly, and smooth, concave downward LREE depletion (Fig. 7).

The volcanic sequence at Barlo, based on observed local stratigraphic relationships, is LSB series volcanics–boninitic basalt–LSB–HSB from base to top (Fig. 3). This volcanic stratigraphy is remarkably similar to holes U1439 and U1442 of IODP Exp. 352. Both the Barlo extrusive section and holes U1439 and U1442 are marked by an abundance of LSB relative to HSB (Reagan et al., 2015). In contrast, the onshore boninite sequence at Ogasawara is dominated by 48–46 Ma HSB and HSB series volcanics interbedded with minor LSB (Maruberivan Formation), which are overlain by 45 Ma LSB and calc–alkaline andesite–dacite (Mikazukiyama Formation) (Kanayama et al., 2012; Taylor et al., 1994; Umino, 1986). Several dikes in the Subic crustal section in the southern San Antonio massif have compositions like Barlo boninitic basalts (Yumul et al., 2000), albeit their petrographic characteristics have not been described. This raises the possibility that boninite is present in other volcanic sections of the Acoje Block as well. The rest of the volcanic sections of the Zambales ophiolite (Coto volcanic section in Tarlac, Sual dikes north of Barlo, and Subic dikes and pillow lavas in the south) are dominated by basalts and basaltic andesites with greater than 0.5 wt % TiO$_2$ which can be classified as moderate-Fe tholeiites (Fig. S1 in the Supplement). The tholeiite dike (B-47 d4) that cross cuts low-silica boninite dikes in the deeper dike swarm section at Barlo is similar in composition and correlative with 44.0 ± 3.0 Ma dikes in
A. Perez et al.: Boninite and boninite-series volcanics in northern Zambales ophiolite

Figure 6. (a–e) MgO, TiO$_2$, FeO$^*$ / MgO, CaO, Al$_2$O$_3$ vs. SiO$_2$ variation diagrams showing the distinct parental magma compositions and modeled fractional crystallization paths of high- and low-silica boninites and boninite-series volcanics. Fractional crystallization paths are modeled using rhyoliteMELTS v.1.2.0 (Ghiorso and Gualda, 2015) at 1 kb pressure and initial fO$_2$ of FMQ + 1. The designated primary boninite magmas given by Umino et al. (2018) are used as parental compositions with an initial H$_2$O content of 1 wt %. Models were run at temperature range of 1500–980$^\circ$C. Modified boninite classification after Kanayama et al. (2013) and Reagan et al. (2015). Dividing lines between boninite and basalt–andesite–dacite–rhyolite (BADR) series are from Pearce and Robinson (2010). (f) Ti–V systematics (Shervais, 1982) of IBM and Zambales subduction initiation rock suites is also shown.

Discussion

6.1 Low-pressure fractionation and magma mixing

Early experimental studies of primitive boninite produced andesitic primary liquids and led to the initial characterization of boninite as a primary magma (Kuroda et al., 1978). Subsequent detailed petrologic analyses resulted in the recognition of the importance of low-pressure fractionation and magma mixing processes to account for the compositional variation of boninite and boninite-series volcanics (Dobson et al., 2006; Taylor et al., 1994; Umino, 1986). Meijer (1980) introduced the concept of the boninite series to describe cogenetic bronzite andesite, dacite and rhyolite formed through the differentiation of boninite, analogous to tholeiitic and calc–alkaline magma series. Figure 6 shows oxide vs. SiO$_2$ variation diagrams of Zambales boninite and boninite series volcanics. Also shown are boninite and boninite-series volcanics from Ogasawara (Kanayama et al., 2012; Nagaiishi, 2008; Taylor et al., 1994; Umino and Nakano, 2007; Yajima and Fujimaki, 2001) and holes U1439 and U1442 of IODP Expedition 352 (Haugen, 2017; Reagan et al., 2015). MgO, TiO$_2$, CaO and Al$_2$O$_3$ contents of HSB and LSB form subparallel trends suggesting distinct parental magma compositions and fractionation paths. Parental HSB is characterized by higher MgO, and lower TiO$_2$, Al$_2$O$_3$ and CaO at a given SiO$_2$ than LSB. HSB is marked by the abundance of orthopyroxene and, in some localities, the presence of clinopyroxene. Umino (1986) describes the crystallization sequence at Chichijima as chromian spinel, olivine, clinopyroxene, enstatite and augite. The HSB differentiation series is best exemplified by samples from Ogasawara and Site 786, ODP Leg 125 (Arculus et al., 1992). Boninite from other notable western Pacific localities such as the Mariana Trench (Bloomer and Hawkins, 1987; Dietrich et al., 1978), Cape Vogel, Papua New Guinea (Jenner, 1981; König et al., 2010),
Nepoui, New Caledonia (Cameron, 1989; Cluzel et al., 2016) and Hahajima Seamount (Li et al., 2013) are all high-silica sub type. Zambales HSB show limited compositional variation with most of the samples collected in an area north of Mt. Sol, possibly from a single volcanic edifice. Conversely, the LSB crystallization sequence is controlled by olivine and clinopyroxene fractionation (Kostopoulos and Murton, 1992; Natland, 1982). The LSB differentiation series is typified by suites from northern Zambales, holes U1439 and U1442 of Expedition 352 and Hole 458, ODP Leg 60 (Meijer, 1982; Sharaskin, 1982). Other LSB and LSB series localities include Facpi Formation in Guam (Reagan and Meijer, 1984), Tonga Trench (Falloon et al., 2007; Falloon and Crawford, 1991), Troodos ophiolite (Cameron, 1985; König et al., 2008; Osozawa et al., 2012; Pearce and Robinson, 2010) and Oman ophiolite (Ishikawa et al., 2002; Kusano et al., 2017, 2014; Nagaishi, 2008).

Using spinel-hosted melt inclusions reported by Umino et al. (2018) as parental magma compositions, isobaric fractional crystallization paths of residual liquids at $+1 \Delta \log$(FMQ) are modeled using rhyoliteMELTS v.1.2.0 (Ghiorso and Gualda, 2015). The compositions of primary spinel-hosted boninitic melt inclusions from Ogasawara (2.1–3.4 wt % $H_2O$) and Guam (3.8 wt % $H_2O$) are in accord with experimental glasses formed by melting synthetic Troodos harzburgite and depleted Tinaquillo lherzolite at 1.5 GPa (Falloon and Danyushevsky, 2000) (Fig. 6). The range of whole-rock HSB compositions can be reproduced by low pressure (1–2 kb) fractional crystallization of parental Ogasawara HSB magmas at lower water content (1 wt %). The $TiO_2$ and $CaO$ contents of Zambales HSB are in the upper end of Ogasawara HSB compositions and can alternatively be produced by fractionation from a parental composition straddling the HSB and LSB boundary of Reagan et
al. (2015). Given a primary LSB magma composition identical to a spinel-hosted melt inclusion from Guam, low pressure (1–2 kb) fractional crystallization at lower water content (1 wt%) can likewise account for the major element variation of Zambales LSB and LSB-series volcanics. The modeled early crystallization of cpx relative to opx and the onset of plagioclase crystallization following cpx at ~57 wt% SiO$_2$ is reflected in the modal compositions of Zambales LSB and LSB-series volcanics (Fig. 4). The occurrence of differentiated LSB series volcanics at the base of the volcanic pile suggests that initial LSB magmas underwent protracted crystal fractionation in magma chambers at depth; the influx of primitive HSB perturbed sub-volcanic magma chambers and likely induced magma mixing. The presence of reversely zoned enstatite microphenocrysts in Zambales HSB, attest to high-level magma mixing between an olivine with orthopyroxene saturated HSB magma and a preexisting LSB series andesitic magma. Zambales HSB deviate slightly from the modeled Ogasawara HSB fractionation paths and lie on a mixing line with potential HSB and LSB-series end-member components having SiO$_2$ contents that do not vary significantly at 58 and 57 wt%, respectively.

The markedly divergent fractionation paths followed by boninite and boninite series volcanics from Barlo and basalts from various volcanic sections of the Zambales ophiolite are shown in the MgO, TiO$_2$ and FeO$^*/$MgO vs SiO$_2$ variation diagrams (Fig. 6). Zambales LSB and LSB series volcanics follow fractionation paths of hydrous primitive arc magmas (Grove et al., 2012). Moderate-Fe tholeiitic basalts and basaltic andesites from the rest of the volcanic sections of the Zambales ophiolite (Evans et al., 1991; Geary et al., 1989; Hawkins and Evans, 1983; Tamayo, 2001; Yumul, 1990) and proto-arc basalts from the Izu–Ogasawara–Mariana forearc (Arculus et al., 2015; Ishizuka et al., 2011; Reagan et al., 2010, 2015) exhibit large FeO$^*/$MgO ratio variation at a restricted SiO$_2$ interval and define a slope steeper than the discriminant line of Miyashiro (1974).

6.2 Slab contributions to a less depleted mantle source

Although there is a general consensus on boninite petrogenesis (Bedard, 1999; Crawford et al., 1989; Pearce et al., 1992), namely that it involves the shallow flux melting of refractory peridotite more depleted than MORB sources, the requisite sub-arc conditions ideal for boninite generation span a range that may involve heterogeneous mantle wedge sources (depleted lherzolite to harzburgite) and the addition of diverse slab-derived components (Cluzel et al., 2016; Kusano et al., 2017; Umino et al., 2015, 2018). We highlight the peculiar trace element characteristics of Zambales boninite; geochemical modeling will be presented elsewhere. Figure 7 shows MORB and chondrite-normalized trace element patterns of Zambales boninite and boninite-series volcanics together with boninite suites from Ogasawara, holes U1439 and U1442 of IODP Expedition 352, Troodos and Oman ophiolites, Nepoui (New Caledonia) and Cape Vogel (Papua New Guinea). Boninite from Zambales, Oman and Troodos ophiolites all show spoon-shaped chondrite normalized REE patterns with heavy REEs that are five to nine times chondrite values. Based on HREE abundances and spinel Cr#, Zambales boninite is derived from a mantle source that is less depleted than Ogasawara boninite (Fig. 7).

Superimposed on the depleted character of boninite are slab-derived components whose nature can be explored using normalized trace element diagrams and trace element ratios with varying compatibilities. The magnitude of hydrous fluid mobile element enrichment in boninite from Ogasawara, Zambales, Oman and Troodos ophiolites are comparable. LREE enrichment is most prominent in Nepoui and Cape Vogel boninites. All boninite suites except for Nepoui and Cape Vogel have elevated Ba/Th ratios (Fig. 8a). Ba is strongly partitioned into aqueous fluids relative to Th, thus is a good proxy for the addition of subduction components released at shallow depths − sz1, Ba-only component of Pearce et al. (2005) (Kepler, 2017; Ribeiro et al., 2015). Increasing Ba/Th ratio is mirrored by increasing Sr/Nd ratio for Zambales, Oman and Troodos boninite (Fig. 8b). Ogasawara, Cape Vogel and Nepoui follow a vertical Th/Yb vector (Fig. 8b) towards sediments − “component 1” of Elliott (2003). We interpret this decoupling as an indicator of increasing contributions from a deep subduction component that is usually characterized as either sediment melt and/or siliceous fluid (Pearce et al., 2005). Zambales boninite and boninite-series volcanics have U/Th ratios (0.62−0.77) much higher than Cape Vogel boninites (0.20−0.29). A high U/Th ratio is associated with saline and oxidizing fluids, while a low U/Th ratio points to the transport of silicarich fluids to source (Kepler, 2017). Zambales and Cape Vogel boninites both have a uniform La/Th ratio of 0.2. In the La/Th vs. Sm/La diagram of Plank (2005) (not shown), Zambales, Oman and Troodos boninites lie on a mixing line between sediments with a Th/La ratio of 0.30 and 0.35 and a mantle source more refractory than MORB with a Sm/La ratio of 1.75. Ogasawara, Cape Vogel and Nepoui boninites may lie on the mixing line between sediments with a Th/La ratio of 0.1 and 0.2 and a highly depleted mantle source with a Sm/La ratio greater than 2. An alternative explanation is that the low Sm/La ratios of Ogasawara, Cape Vogel and Nepoui boninites dominantly reflect LREE enrichment which masks the mixing relationship. The shared characteristics of Zambales, Oman, and Troodos boninites are further exemplified by subchondritic bulk Earth Nb/Ta ratios with low Zr/Hf and Zr/Sm ratios (<30) characteristic of depleted mantle (Münker et al., 2003; Weyer et al., 2003; Zanetti et al., 2006) (Fig. 8c). The high Zr/Sm ratios (>40) of Ogasawara, Cape Vogel and Nepoui boninites have been ascribed to the presence of residual amphibole in the slab (Cluzel et al., 2016; König et al., 2010; Pearce et al., 1992). In summary, trace element ratios show that aqueous fluids are the dominant slab components in Zambales boni-
nite and boninite series volcanics. This is corroborated by the enriched Pb and Sr isotopic compositions of the Acoje Block’s uppermost crustal differentiates and cumulate ultramafic samples that do not show an inverse relationship with Nd isotopic compositions (Encarnación et al., 1999).

6.3 Subduction initiation origin of the Zambales ophiolite

The 45 Ma crustal section of the Coto Block has a composition transitional to mid-ocean ridge basalt (MORB) and island arc tholeiite (IAT). On the basis of immobile element-based trace element discrimination diagrams, Coto Block dikes and lavas from Tarlac are robustly characterized as distinct from Mariana Trough back-arc basin basalts (Geary et al., 1989). Decreasing REEs, TiO$_2$, Zr and Y in Coto volcanics, dikes in the Coto mantle section to Acoje volcanics document the progressive depletion of the mantle source in Zambales mantle wedge (Yumul, 1990). Succeeding zircon U–Pb geochronology established the 1–2 Myr age difference between Coto and Acoje blocks (Encarnación et al., 1993). Thus, combined geochemical and age constraints preclude a back-arc basin origin for Coto Block as forwarded by Hawkins and Evans (1983), and are more compatible with a proto-forearc setting as originally suggested by Geary et al. (1989). Coto Block volcanics ($n = 9$) have variable Ti / V ratios, mostly between 20 and 26 (Fig. 6f). Recognizing the small sample size, this range is higher than proto-arc basalts (PAB) and overlaps with MORB (Fig. S2a); this suggests a less oxidized source than IBM PAB (Brounce et al., 2015; Hickey-Vargas et al., 2018; Mallmann and O’Neill, 2009). The corresponding Ti$_8$ and Si$_8$ values of the Coto Block are comparable with proto-arc basalts from the Bonin Ridge, Mariana Trench slope, Hole U1430 of IODP Exp. 351 and Hole 1440 of IODP Exp. 352 (Arculus et al., 2015; Ishizuka et al., 2011; Reagan et al., 2010, 2015) (Fig. 9). Si$_8$ and Ti$_8$ values of Coto Block basalts are also distinct from Celebes Sea basin and West Philippine basin MORB (Pearce et al., 2005; Savov et al., 2006; Serri et al., 1991; Spadea et al., 1996; Zakariadze, 1981). In addition, the primitive mantle-normalized fluid immobile trace element abundances of Coto Block volcanics are also exceptionally low and more depleted compared to MORB (Hickey-Vargas et al., 2018) and Celebes Sea basin basalts (Fig. S2b). From field observations, oceanic accretion can be inferred from the Coto crustal section based on a well-developed sheeted dike complex, in contrast to the mutually intrusive dikes of the Acoje crustal section. With the recognition of boninite and boninite-series volcanics (Barlo), and moderate-Fe arc tholeiites (Barlo-Sual, Subic) in the crustal section of Acoje Block, it is apparent that subduction initiation chemostratigraphy (Ishizuka et al., 2011; Whattam and Stern, 2011) is present in the Zambales ophiolite as well. Although stratigraphic relationships of individual volcanic sections may be obfuscated by emplacement-related tectonic deformation, by considering available age constraints, the crustal sections of the Zambales ophiolite represent proto-arc accretion and juvenile arc sections supplied by separate magma plumbing systems as observed at IODP Exp. 352 sites (Reagan et al., 2015).

6.4 Doubly vergent subduction initiation

Previous attempts to ascertain the provenance of Zambales ophiolite focused on its characterization as a marginal basin and thus linked it to the surrounding Eocene marginal basins such as the Celebes Sea basin and Molucca Sea basin. In the most comprehensive petrological and geochemical study of
Philippine ophiolites, Tamayo et al. (2004) noted the strong subduction geochemical imprint of Zambales ophiolite and placed it as a marginal basin between the Celebes Sea basin and the western margin of the Philippine Sea plate. The difficulty in reconstructing the Paleogene tectonic configuration of the southeast Asian region, specifically the spreading history of the oceanic domain east of Sundaland and west of the Philippine Sea plate, stems from the fact that this region has been fully consumed along convergent margins east of southeastern Eurasia (Zahirovic et al., 2014). This gap was addressed by Wu et al. (2016) through the novel use of structural unfolding of subducted slabs imaged by seismic tomography. In their preferred model (model 1b), unfolding of subducted slabs beneath southern Eurasia reveals that the Philippine Sea plate was bordered by Cretaceous oceanic crust (the East Asian Sea) in its western margin. Paleomagnetic data derived from sites in the Philippine Sea plate show northward translation concomitant with clockwise rotation (Hall et al., 1995; Richter and Ali, 2015; Yamazaki et al., 2010) (Fig. 10a). Eocene to Miocene sites from Luzon indicate similar northward migration; thus, the island can be regarded as the western promontory of the Philippine Sea plate (Queano et al., 2007). The subequatorial position of Luzon during the middle Eocene is further supported by paleomagnetic data from pillow lavas forming the basement of Luzon Central Cordillera (K–Ar age: 45.49 ± 2.27 Ma) that yield a paleolatitude of 6.3 ± 3° S (Queano et al., 2009; Sajona, 1995). East of Luzon and forming the greater part of Philippine Sea plate, the West Philippine basin (WPB) is characterized as a back-arc basin formed between opposing subduction zones (Deschamps and Lallemand, 2002). Pre-Eocene subduction south of WPB possibly generated the Mesozoic arc terranes in the Philippine Sea plate including Amami Plateau and Daito Ridge as well as the Cretaceous ophiolites in the eastern Philippines (Lallemand, 2016). Initiation of a long-lived subduction east of the WPB produced the Izu–Ogasawara (Bonin)–Mariana (IBM) forearc above a west-dipping subduction zone (Ishizuka et al., 2011). It is in this context that we re-evaluate the origin of Zambales ophiolite.

Tilt-corrected inclination data from sites in the 44 Ma Acoje Block equate to equatorial paleolatitudes (Fuller et al., 1991). Adopting southerly paleolatitudes in consonance with the modeled Luzon translation history of Wu et al. (2016), we make a case for the subduction initiation origin of the Zambales ophiolite in the leading edge of the northwestward-moving, clockwise-rotating Philippine Sea plate. In this scenario, the origin of Philippine Sea plate boninites (IBM and Zambales) would be in a doubly vergent subduction initiation setting (Fig. 10b). In contrast with IBM, incipient subduction which produced Zambales ophiolite proto-arc basalts, boninites and arc tholeiites within 3 Ma is rather short-lived and alludes to rapid emplacement. The timing of the proposed subduction initiation in the western margin of Philippine Sea plate is yet to be constrained. The late Oligocene to early Miocene onset of true basal sedimentation in the Central Valley basin provides a minimum docking age between Zambales ophiolite and eastern Luzon (Bachman et al., 1983). The GPlates-based reconstruction presented here, using unfolded slab data (Wu et al., 2016), is essentially similar to the Philippine Sea plate evolutionary models of Deschamps and Lallemand (2003). Although it is beyond the scope of this study to identify the nature of a preexisting structural boundary as a transform fault or strike-slip extension of a subduction zone, we note that both Zambales and IBM are orthogonal to the West Philippine basin spreading center and the Cretaceous arc terranes in the overriding plate. Contrary to a subduction initiation origin, Lallemand (2016) posits that proto-arc basalts (or forearc basalts) formed in short-lived Eocene oceanic basins (e.g., Kita–Daito and Minami–Daito basins) bounded by the Cretaceous arc terranes. We believe that this might be the case for Eocene ophiolites in eastern Philippines (e.g., Angat ophiolite) but not for the Zambales ophiolite. The early Eocene age (48.1 ± 0.5 Ma) of Angat ophiolite does not necessarily prove an affinity with Zambales as suggested by Encarnación et al., (1993), rather it simply demonstrates that basin complexes in the Philippine Mobile Belt consists of juxtaposed geochemically distinct Eocene and Cretaceous ophiolites (ophiolite belts 1B and 1C of Tamayo et al., 2004) (Fig. 1a). Slightly older Eocene ages (e.g., 50.83 ± 3.35 Ma) were obtained by subsequent whole-rock
K–Ar and SHRIMP zircon U–Pb dating of ophiolitic samples from eastern Luzon (Sajona, 1995; Tani et al., 2015). In addition, these Cretaceous and Eocene ophiolites are associated with Eocene volcano–sedimentary arc sequences (Caraballo, Maybangain, Anawan and Payo formations) (Billedo et al., 1996; David et al., 1997). This differs sharply with the deep-marine, isolated environment deduced from the Eocene sedimentary carapace of the Zambales ophiolite (Schweller and Karig, 1982).

Although current terrestrial subduction is dominantly asymmetric, it is interesting to note that two-sided subduction is what is essentially produced in 2-D and 3-D models of mantle convection (Gerya et al., 2008; Wada and King, 2015). Likewise, we discern that doubly vergent subduction initiation (SI) geometry or subduction initiation with oppositely dipping subduction zones along its margins is characteristic of 3-D thermomechanical models of plume-induced subduction initiation (Baes et al., 2016; Gerya et al., 2015). Plume-induced subduction initiation was first recognized by Whattam and Stern (2015) to describe the temporal association of late Cretaceous plume-related oceanic plateaus in Central America which was followed by arc volcanism with oppositely dipping slab dispositions. In the case of the Eocene western Pacific, a mantle plume centered on the Manus Basin had originally been invoked by Macpherson and Hall (2001) to account for an inferred thermal anomaly in IBM boninite mantle source, implicitly connecting the initiation of the IBM arc to the presence of a mantle plume. Isotopic studies are in agreement that a mantle plume is likely associated with the oceanic plateaus and bathymetric highs emplaced at the same time as the opening of the West Philippine basin (Hickey-Vargas et al., 2006; Ishizuka et al., 2013); however, thermal anomalies in excess of the ambient mantle are not reflected in mantle potential temperature estimates of proto-arc basalt from the IBM forearc (Umino et al., 2018). A causative link between a mantle plume and the doubly vergent SI configuration along Philippine Sea plate margins is yet to be established. We speculate that the location of Philippine Sea plate (PSP) in the nexus of the Pacific, Indo-Australian and Eurasian plates and their long-term Cenozoic plate motion makes doubly vergent subduction initiation along its margins feasible. The northwestward translation and clockwise rotation of the Philippine Sea plate starting in the early Eocene had to be accommodated by the adjoining oceanic domain east of southern Eurasia (e.g., East Asian Sea); hence, its interaction with the oceanic leading edge of the Philippine Sea plate is expected (Wu et al., 2016; Zahirovic et al., 2016) and likely led to incipient subduction (Fig. 10). The dynamics of sustained double-vergent subduction is examined by Holt et al. (2017) but doubly vergent subduction initiation is yet to be explored by numerical modeling. Field and petrologic data presented here demonstrate that models of subduction initiation based on the IBM forearc are currently simplistic. Geodynamic models of subduction initiation should be founded on robust geologic data and a doubly vergent SI configuration based on the Zambales ophiolite provides another boundary condition for refined models of SI along PSP margins. We advocate that geodynamic models of subduction initiation along Philippine Sea plate margins incorporate a pre-Eocene, N–NE-dipping subduction zone (the proto West Philippine trench of Faccenna et al., 2010) associated with Cretaceous terranes forming the
overriding plate, doubly vergent subduction initiation along its margins as well as the interplay of plate forces and mantle upwelling (e.g., Oki-Daito plume of Ishizuka et al., 2013) during incipient subduction (Fig. 10b).

7 Conclusions

1. The extrusive sequence in the juvenile arc section of the Zambales ophiolite in Luzon Island in the Philippines consists of boninite and boninite-series volcanics. This makes northern Zambales ophiolite the lone middle Eocene boninite locality in the Philippine Sea plate apart from the Ogasawara islands, Guam and their submarine equivalent in the IBM forearc.

2. Zambales boninite and boninite series volcanics are marked by low trace element abundances relative to mid-ocean ridge basalt with hydrous fluid mobile element enrichment and heavy rare earth element depletion, which is comparable with boninite from Troodos and Oman. Trace element ratios suggest that aqueous fluids released from shallow sub-arc depths are the dominant slab components in Zambales boninite.

3. Subduction initiation stratigraphy deduced from diving, dredging and drilling programs in the Izu–Ogasawara (Bonin)–Mariana forearc is recognized in the Zambales ophiolite as well. The temporal variation from proto-arc basalt to boninite and post-boninite arc tholeiite is represented by the Coto (45 Ma), Barlo (44 Ma) and Sual–Subic (44–43 Ma) volcanic sections of Zambales ophiolite. Incipient subduction associated with the juvenile arc in the northern Zambales ophiolite likely involved the unfolded East Asian Sea crust as the subducting slab and the westernmost margin of Philippine Sea plate as the overriding plate.

4. By studying the Zambales ophiolite, it can be shown that subduction initiation is a plate-scale process. To address Eocene western Pacific subduction initiation, it is essential to consider not just the Izu–Ogasawara–Mariana forearc but also geologic constraints from the entire Philippine Sea plate. Doubly vergent subduction initiation deduced from the rock record is a testable mechanism that can be explored by geodynamic modeling.
